ABSTRACT

Microsporidia are common pathogens of insects and sometimes are considered as a candidate in the biological control of mosquitoes. Recently a microsporidium infection was discovered in *Anopheles superpictus* (Diptera: Culicidae) larvae, in Iran. The responsible agent belonged to the genus *Parathelohania* (Microsporidia: Amblyosporidae). This study has been carried out to identify its identity at the species level.

Fresh infected larvae were collected from the type locality, Kiar district, in Chahar Mahal and Bakhtiari province, at the central western of Iran. Superficial and the internal ultrastructure of the recovered spores were explored by scanning and transmission electron microscopy, respectively. Molecular techniques were also employed to amplify parts of its ssu rDNA. The obtained data were compared with the available information of congener species and other closely related microsporidia to elucidate evolutionary relationship.

A small apical depression and two posterolateral ridges extending backward from a pear shaped anterior body mass were notable under scanning electron microscopy. Transmission electron microscopy revealed 2 broad and 3–4 narrow coils in the either side of spores, respectively. The sequence of a 1062 nucleotide fragment of ssu rDNA was determined by means of PCR technique.

This study indicates that the microsporidium infecting *An. superpictus* differs from other previously described species in the genus *Parathelohania*. It means that the microsporidium infecting *An. superpictus* is a new species and hereby it is called *Parathelohania iranica*. Further work is necessary to clarify its life cycle and probable value in the biological control of mosquitoes.

1. Introduction

Mosquitoes are commonly considered the most important disease vectors in the world (Mullen and Durden, 2009). While they transmit a wide range of pathogens to humans and livestock, they are parasitized in turn by a diverse group of microbial agents including microsporidia (Roberts and Castillo, 1980).

Microsporidia are a large group of intracellular, eukaryotic parasites closely related to fungi (Corradi and Keeling, 2009) and are among the most common and widely distributed parasites of mosquitoes in nature. To date, more than 179 species of microsporidia in 25 different genera are recognized as infective to at least 14 genera of mosquitoes (Andreadis, 2007; Andreadis et al., 2012, 2013).

Recently, a microsporidium infection in *Anopheles superpictus* Meigen larvae was reported from Iran (Omrani et al., 2016). To our knowledge, there is no other report on such an infection in this

mosquito species. *Anopheles superpictus* is a malaria vector in the Middle East (Sinka et al., 2010) including Iran (Edrissian, 2006) and has a widespread distribution in the Palearctic region (Zahar, 1974).

Preliminary observations on the light microscopic features of the spores (i.e. bottle shape appearance and aggregation in clusters of 8) suggested a species belonging to the genus *Parathelohania* Codreanu (1966) (Codreanu, 1966; Hazard and Anthony, 1974; Omrani et al., 2016). *Parathelohania* accounts for a relatively large genus within the family Amblyosporidae (Becnel and Andreadis, 2014). The members of this genus are largely restricted to anopheline mosquitoes, have polymorphic spores and an obligatory intermediate copepod host in their life cycle (Andreadis, 2007).

Although light microscopy is a primary tool in the general recognition of microsporidia, species identification requires further visualization of the internal ultrastructure by transmission electron microscopy (Garcia, 2002). Additionally, molecular methods determining the

nucleotide sequence of ssu rDNA provide confirmation on its unique identity and invaluable information on its phylogenetic relationship with the other known microsporidia species (Vossbrinck and Debrunner-Vossbrinck, 2005).

The present study provides taxonomic identification of this newly discovered microsporidium at the species level based on its ultrastructural and molecular characteristics.

2. Materials and methods

2.1. Field collection and host identification

The type locality was visited to collect fresh infected *An. superpictus* larvae. The larval habitat is located at the Helen Protected Area, bordering Kiar district in Chahar Mahal and Bakhtiari province, Iran. All visits were made during August to September 2013. Infected 3rd or 4th instar anopheline larvae were collected from a shallow leakage pool nearby a small spring. They were placed in a black pan and examined for the whitish discoloration of their thorax and/or abdominal segments as the common gross diagnostic sign of microsporidium infection (Andreadis, 2007). The species identity of the larvae was verified in the laboratory with the use of a valid local identification key (Azari-Hamidian and Harbach, 2010).

2.2. Electron microscopy

For transmission electron microscopy, the affected body segments of a typical infected larva were fixed in 2.5% (v/v) glutaraldehyde for 24 h at 4 °C. They were buffered, then, in 200 mM sodium cacodylate (pH 7) and postfixed in aqueous 1% (w/v) OsO₄ (pH 7.4) for 1 h at room temperature. After washing the specimens in sodium phosphate buffer (pH 7) they were dehydrated through a graded ethanol series and embedded in epoxy resin plus propylene oxide (1:1). Thin sections (~60–100 nm) were stained with 2% (w/v) uranyl acetate in 50% ethanol followed by 1% lead citrate and examined under CM-30 transmission electron microscope (Philips, United States) at an accelerating voltage of 150 kV.

For scanning electron microscopy no specific preparation was made. The freshly dried spores were coated with gold and viewed under XL30 scanning electron microscope (Philips, United States) at an accelerating voltage of 20 kV.

2.3. Molecular investigations

Ten milliliters of the water containing 2–3 ruptured dead larvae was filtered through a 10 µm nylon mesh to collect their infecting spores. The collected material was washed with tap water and centrifuged at 12,000 rpm for 10 min and the aliquot was discarded. 150 µl of TAE buffer (containing Tris-Acetate 0.04 M and EDTA 0.001 M) plus 150 mg 0.1 N hydrochloric acid washed fine ground glass (300–500 µm) were added to the precipitate in a clean 1.5 ml microtube. The microtube was shaken vigorously in a high speed vortex machine for 50 s and then incubated for 3 min at 95 °C on a hot plate. The adequacy of the concentration of extracted DNA was verified by Nanodrop® microspectrophotometer.

The NCBI GenBank was checked for species specific ssu rDNA sequences in the genus *Parathelohania*. In this respect, the relevant sequences of four species i.e. *P. anophelis* (AN: AF027682.1), *P. obesa* (AN: AY090065.1), *P. divulgata* (AN: JF826420.1) and *P. tomski* (AN: JF826421.1) were aligned by Chromas 2.3 software and GTGGATGCTCGCCTTAAAGAC and CCAATCTAGCAGCACGGATTC were designed as the forward and reverse primers, respectively.

PCR reaction was performed in 25 µl final volume containing 2.4 µl of 1X PCR buffer, 1 µl 100 mM MgCl₂, 0.5 µl 10 mM dNTP, 0.1 µl 3 unit per microliter of Taq polymerase (Kowsar Biotech Company, Iran) and 0.5 µl of each primers. Amplification was carried out in Corbett thermal

cycler (CG1-96, Australia) under condition, 95 °C for 5 min followed by 5 cycles of 95–59–72 °C for 90 s, 30 cycles of 95–59–72 °C for 60 s, and final extension of 72 °C for 6 min. Eight microliters of PCR product was electrophoresed on 1% of agarose gel and visualized after ethidium bromide staining. PCR product was sequenced using ABI 3730 sequencer (Applied Biosystems, Macrogen, South Korea). The result was compared with the data available for other known *Parathelohania* species to calculate the percentage of similarity using Clustal Omega Software. The evolutionary history for *Parathelohania* species and selected closely related microsporidia as outgroups i.e. *Novothelohania ovalae* (JF837528), *Takaokaspora nipponicus* (KF110990) and *Senoma globulifera* (DQ641245) was inferred using the UPGMA method. The bootstrap consensus tree inferred from 1000 replicates was taken to represent the evolutionary history of the taxa analyzed. The evolutionary distances were computed using the Maximum Composite Likelihood method. All positions containing gaps and missing data were eliminated. Evolutionary analyses were conducted in MEGA6 software.

3. Results and discussion

The scanning electron micrographs showed that there is a small apical depression over the bulged and pear shaped body mass of spores (Fig. 1). Two posterolateral ridges are extended from the latter towards the rear where they coalesce to form a complex structure. Comparison with the corresponding transmission electron micrographs shows that this structure is an expanded thin floppy layer asymmetrically stretched out from the periphery of the posterior projection of spore body mass.

The fine superficial structure of spores resemble *P. africana*, *P. anophelis*, *P. obesa* and *P. octolagenella*, the only other members of *Parathelohania* for which published scanning electron micrographs are available. Apart from coarse markings on the pear-shaped body mass of spores, the presence of a shrunken posterior part is notable. However, the actual spatial structure of this part is not clear and more information is needed to elucidate its real configuration and the functional role in such a typical *Parathelohania* species.

Under transmission electron microscope, spore aggregates were detected within a well-defined sporophorous vesicle (Fig. 2). The bilayer wall of spores was such that the granular outer layer (exospore) was absent on the anterior end of the spore and the hyperlucent inner layer (endospore) was prominently bulged at the posterior end. In addition to the anchoring disk, lamellar polaroplast, polar filament and the posterior vacuole, 2 broad and 3–4 narrow coils were recognizable in the either side of spores. This polar filament configuration differs from all other *Parathelohania* species with known coil ultrastructure

Fig. 1. The scanning electron micrograph of a typical spore of *P. iranica* sp. nov. in *An. superpictus* larva.

Fig. 2. TEM micrographs of *P. iranica* sp. nov. spore infecting *An. superpictus* larva. Top row: Mature spores with 2 broad and 3–4 narrow coils in the either side. Arrows are pointing at the sporophorous vesicle. Bottom row: High resolution of different parts of mature spores. Exospore (ex), endospore (en), posterior end (pe), broad (bc) and narrow coils (nc), polar filament (pf), anchoring disc (ad), lamellar polaroplast (lp) and posterior vacuole (pv).

except for *P. africana* (Table 2). However, this species has smaller meiospores ($3.7 \times 2.3 \mu\text{m}$) and its type locality is Nigeria, Africa. It is also known that it parasitizes *An. gambiae*.

Out of 23 named *Parathelohania* species in the literature, the information of the coil structure of only 14 species is available (Table 2).

Parathelohania evansae and *P. aquasalensis*, both with 5 broad and 4 narrow coils have the highest number of broad coils in the genus *Parathelohania*. On the other side, *P. africana*, *P. chagrasiensis*, *P. detinovae*, *P. divulgata*, *P. formosa*, *P. illinoiensis*, *P. octolagenella*, *P. sibirika*, *P. teguldeti* and *P. tomski* with 2 broad and from 3 up to 6 narrow coils have the least number of broad coils in the genus. Other *Parathelohania* species take a place somewhere between these two extremes. In general, this figure indicates that South American species have 5 and Asian species have 2 broad coils. No such a specific pattern is recognizable for other species in the group. The number of broad coils in the microsporidium infecting *An. superpictus* larvae is in the range of Asian species.

The equal number of polar filament coil configuration in some *Parathelohania* species is interesting. For example, *P. chagrasensis*, *P.*

illinoiensis and *P. sibirika* all have 2 broad and 4 narrow coils. *Parathelohania formosa*, *P. teguldeti* and *P. tomski* also have 2 broad and 4.5–5 narrow coils. On the other side, the mosquito host is also not species specific. For instance, both of *P. formosa* and *P. teguldeti* infects *An. messeae*. In fact, although the number and arrangement of the coils in *Amblyospora* species seems to be unique for each species that has been examined so far (Andreadis, 1994) this does not appear to be true for the *Parathelohania* as the total number of coils are generally much fewer. Based on these limitations, some authors have used additional ultrastructural characters in the species identification process. For example, Simakova and Pankova (2004) described the shape of cross-sectioned posterior end, the size of bottle-neck projection, the structure of spore wall, the morphology of cytoplasmic inclusions, the structure of polaroplast, and the process of spore development in sporophorous vesicle in the differentiation of 5 new species of the genus *Parathelohania*.

Although almost all of the named and unnamed *Parathelohania* species have Anopheline mosquito hosts (Table 2) (Sprague et al., 1977), *Parathelohania barra*, *P. costatus* and *P. chagrasensis* are exceptions to this general rule. Since, there is no published information on the ultrastructure and the developmental stages of the first two species; it might be assumed that *P. chagrasensis* is the only valid *Parathelohania* species which has a non-anopheline mosquito host. It is obvious that the molecular data is required to confirm the conspecificity or uniqueness. The microsporidium species of the present investigation parasitizes *An. superpictus* which is a new anopheline host for *Parathelohania* species and it is the first report of microsporidium infection in this malaria mosquito.

With the aid of specific primers, a 1062 nucleotide fragment of the ssu rDNA was amplified by PCR technique. The sequence of this

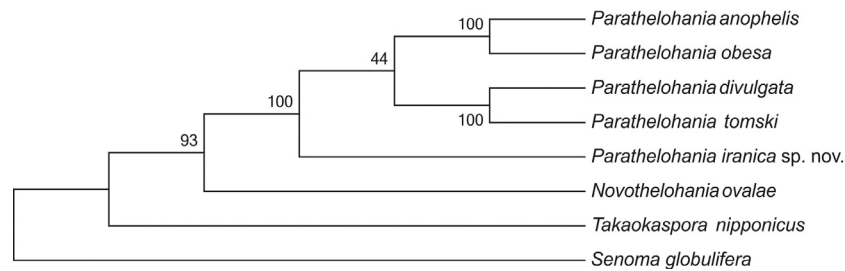

Fig. 3. Phylogenetic tree of *Parathelohania* species and the closely related microsporidia.

fragment was submitted to the GenBank and recorded under the accession number KM2777793. The under study-microsporidium partial fragment was 7.48–8.14% different from other *Parathelohania* species (Table 1).

Phylogenetic analysis of the under-investigation microsporidium reveals that it is a distant taxon to the other *Parathelohania* species with known ssu rDNA sequence (Fig. 3). It is also outgroup to other closely related microsporidia. This strongly supports the morphological and ecological findings that suggest the microsporidium infecting *An. superpictus* larvae is a new species. The monophyletic relationship of *P. anophelis* with *P. obesa* and also *P. divulgata* with *P. tomski* was previously recognized by Andreadis et al. (2012).

We have described here the ultrastructure and molecular aspects of the microsporidium infecting *An. superpictus* larvae. These data in addition to the ecological information on the type locality and the mosquito host of this microsporidium indicate that it is a new member for the genus *Parathelohania*. Seyed-Mohammad Omrani and Seyedeh-Fatemeh Moosavi are responsible for the new taxon and propose that it be named *Parathelohania iranica* sp. nov.. Future works should focus on the life cycle of this microsporidium in both mosquito and copepod hosts as this information could further support this conclusion.

4. Taxonomic summary

Parathelohania iranica sp. nov. Omrani and Moosavi.

Type host: *Anopheles superpictus* Meigen (Diptera: Culicidae).

Type locality: Helen Protected Area, Kiar district, Chahar Mahal and Bakhtiari province, central western part of Iran.

Site of infection: Fat body (Omrani et al., 2016).

Diagnosis: Bottle-shaped semioval spores, in groups of eight and within sporophorous vesicles are ranged $4.33 \pm 0.19 \mu\text{m} \times 2.67 \pm 0.12 \mu\text{m}$ and $4.18 \pm 0.43 \mu\text{m} \times 2.45 \pm 0.33 \mu\text{m}$ in wet and fixed preparations, respectively. An asymmetrical folding is stretched out at the periphery of posterior projection. The spores are uninucleate, with a thick wall and large posterior vacuole. The exospore with spongy texture has smooth surface and covers dense endospore. While the former has different thickness at different parts of the spores, the latter is equally thick everywhere except for the posterior projection. Polaroplast is lamellate and horizontally stacked starting from the apical region up to the vicinity of posterior vacuole. Three different zones with relatively the same size are recognizable within the polaroplast. The first zone is characterized by thicker lamellae. The lamellae of the second zone are thinner and compact. In the third zone lamellae are not well defined and are comprised of packets irregularly intermingled with each other. Polar filament is anisofilar with 2 broad proximal and 4 narrow distal coils (sometimes 3 in one side) all arranged in a single row.

Type material: Holotype in the form EM block, with reference number AS130909-H; and paratypes in the form of stained slides and 70% alcohol-preserved infected larvae with reference number AS130909-Ps are kept at the Department of Medical Parasitology, Shahrekord University of Medical Sciences, Shahrekord, Iran. Live specimens are also maintained in the fridge of the same laboratory.

Gene sequence: Partial fragment sequence of the ssu rDNA is

retrievable from the GenBank/EMBL database with the accession No. KM2777793.

Etymology: The species is named in recognition of the country wherein it was discovered.

Acknowledgements

The authors are grateful to Dr. Theodore G. Andreadis, Center for Vector Biology & Zoonotic Diseases, Connecticut, United States, for his kind contribution on the verification of the presented microsporidium as a new species. Mr. Mostafa Meghdari, Tarbiat Modares University, Tehran, Iran and Mrs. Mahshid Shafiezhadeh, Institute of Biochemistry and Biophysics, University of Tehran, Tehran, Iran are appreciated for their assistance in the preparation and photography of specimens for SEM and TEM electron microscopy. The authors also wish to thank Prof. Morteza Hashemzadeh-Chaleshtori, Cellular and Molecular Research Center, Shahrekord University of Medical Sciences, Shahrekord, Iran, for reviewing the manuscript. We would like to express our gratitude to anonymous reviewers for their kind help to improve the manuscript. This paper is a part of the results of the second author to fulfill MSc degree on medical parasitology from Shahrekord University of Medical Sciences. This work was financially supported by Shahrekord University of Medical Sciences [Grant No. 1820-74-01-1392]. The authors declare that there is no conflict of interest.
